Package 'energy'

April 19, 2022

Description E-statistics (energy) tests and statistics for multivariate and univariate inference, including distance correlation, one-sample, two-sample, and multi-sample tests for comparing multivariate distributions, are implemented. Measuring and testing

Title E-Statistics: Multivariate Inference via the Energy of Data

Version 1.7-10 **Date** 2022-04-18

multivariate independence based on distance correlation, partial distance correlation, multivariate goodness-of-fit tests, k-groups and hierarchical clustering based on energy distance, testing for multivariate normality, distance components (disco) for non-parametric analysis of structured data, and other energy statistics/methods are implemented.

centering distance matrices

Double centering and U-centering

Description

Stand-alone double centering and U-centering functions that are applied in unbiased distance covariance, bias corrected distance correlation, and partial distance correlation.

Usage

Dcenter(x)

Ucenter(x)

U_center(Dx)

D_center(Dx)

Arguments

x dist object or data matrix

Dx distance or dissimilarity matrix

Details

In Dcenter and Ucenter, x must be a dist object or a data matrix. Both functions return a doubly centered distance matrix.

Note that pdcor, etc. functions include the centering operations (in C), so that these stand alone versions of centering functions are not needed except in case one wants to compute just a double-centered or U-centered matrix.

U_center is the Rcpp export of the cpp function. D_center is the Rcpp export of the cpp function.

Value

All functions return a square symmetric matrix.

Dcenter returns a matrix

$$A_{ij} = a_{ij} - \bar{a}_{i.} - \bar{a}_{.j} + \bar{a}_{..}$$

as in classical multidimensional scaling. Ucenter returns a matrix

$$\tilde{A}_{ij} = a_{ij} - \frac{a_{i.}}{n-2} - \frac{a_{.j}}{n-2} + \frac{a_{..}}{(n-1)(n-2)}, \quad i \neq j,$$

with zero diagonal, and this is the double centering applied in pdcov and pdcor as well as the unbiased dCov and bias corrected dCor statistics.

Note

The c++ versions D_center and U_center should typically be faster. R versions are retained for historical reasons.

```

Examples

```
x <- iris[1:10, 1:4]
dx <- dist(x)
Dx <- as.matrix(dx)
M <- U_center(Dx)

all.equal(M, U_center(M))  #idempotence
all.equal(M, D_center(M))  #invariance</pre>
```

dcorT

Distance Correlation t-Test

Description

Distance correlation t-test of multivariate independence for high dimension.

Usage

```
dcorT.test(x, y)
dcorT(x, y)
```

Arguments

x data or distances of first sampley data or distances of second sample

Details

dcorT.test performs a nonparametric t-test of multivariate independence in high dimension (dimension is close to or larger than sample size). As dimension goes to infinity, the asymptotic distribution of the test statistic is approximately Student t with n(n-3)/2-1 degrees of freedom and for $n \ge 10$ the statistic is approximately distributed as standard normal.

The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values.

The t statistic (dcorT) is a transformation of a bias corrected version of distance correlation (see SR 2013 for details).

Large values (upper tail) of the dcorT statistic are significant.

dcorT 5

Value

dcorT returns the dcort statistic, and dcorT. test returns a list with class htest containing

method description of test
statistic observed value of the test statistic
parameter degrees of freedom
estimate (bias corrected) squared dCor(x,y)
p.value p-value of the t-test

data.name description of data

Note

```
dcor.t and dcor.ttest are deprecated.

6 dcov.test

dcov.test

Distance Covariance Test and Distance Correlation test

Description

Distance covariance test and distance correlation test of multivariate independence. Distance covariance and distance correlation are multivariate measures of dependence.

Usage

```
dcov.test(x, y, index = 1.0, R = NULL)
dcor.test(x, y, index = 1.0, R)
```

Arguments

x data or distances of first sample
y data or distances of second sample

R number of replicates

index exponent on Euclidean distance, in (0,2]

Details

dcov.test and dcor.test are nonparametric tests of multivariate independence. The test decision is obtained via permutation bootstrap, with R replicates.

The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values. Arguments x, y can optionally be dist objects; otherwise these arguments are treated as data.

The dcov test statistic is $n\mathcal{V}_n^2$ where $\mathcal{V}_n(x,y) = \text{dcov}(x,y)$, which is based on interpoint Euclidean distances $\|x_i - x_i\|$. The index is an optional exponent on Euclidean distance.

Similarly, the dcor test statistic is based on the normalized coefficient, the distance correlation. (See the manual page for dcor.)

Distance correlation is a new measure of dependence between random vectors introduced by Szekely, Rizzo, and Bakirov (2007). For all distributions with finite first moments, distance correlation \mathcal{R} generalizes the idea of correlation in two fundamental ways:

- (1) $\mathcal{R}(X,Y)$ is defined for X and Y in arbitrary dimension.
- (2) $\mathcal{R}(X,Y) = 0$ characterizes independence of X and Y.

Characterization (2) also holds for powers of Euclidean distance $||x_i - x_j||^s$, where 0 < s < 2, but (2) does not hold when s = 2.

Distance correlation satisfies $0 \le \mathcal{R} \le 1$, and $\mathcal{R} = 0$ only if X and Y are independent. Distance covariance \mathcal{V} provides a new approach to the problem of testing the joint independence of random vectors. The formal definitions of the population coefficients \mathcal{V} and \mathcal{R} are given in (SRB 2007). The definitions of the empirical coefficients are given in the energy dcov topic.

dcov.test 7

For all values of the index in (0,2), under independence the asymptotic distribution of $n\mathcal{V}_n^2$ is a quadratic form of centered Gaussian random variables, with coefficients that depend on the distributions of X and Y. For the general problem of testing independence when the distributions of X and Y are unknown, the test based on $n\mathcal{V}_n^2$ can be implemented as a permutation test. See (SRB 2007) for theoretical properties of the test, including statistical consistency.

Value

dcov.test or dcor.test returns a list with class htest containing

method description of test

statistic observed value of the test statistic

estimate dCov(x,y) or dCor(x,y)

estimates a vector: [dCov(x,y), dCor(x,y), dVar(x), dVar(y)]

condition logical, permutation test applied replicates replicates of the test statistic p.value approximate p-value of the test

n sample size

data.name description of data

Note

For the dcov test of independence, the distance covariance test statistic is the V-statistic n dCov² = nV_n^2 (not dCov).

```

dcov2d

Fast dCor and dCov for bivariate data only

Description

For bivariate data only, these are fast O(n log n) implementations of distance correlation and distance covariance statistics. The U-statistic for dcov^2 is unbiased; the V-statistic is the original definition in SRB 2007. These algorithms do not store the distance matrices, so they are suitable for large samples.

Usage

```
dcor2d(x, y, type = c("V", "U"))

dcov2d(x, y, type = c("V", "U"), all.stats = FALSE)
```

Arguments

```
x numeric vector
y numeric vector
type "V" or "U", for V- or U-statistics
all.stats logical
```

Details

The unbiased (squared) dcov is documented in dcovU, for multivariate data in arbitrary, not necessarily equal dimensions. dcov2d and dcor2d provide a faster O(n log n) algorithm for bivariate (x, y) only (X and Y are real-valued random vectors). The O(n log n) algorithm was proposed by Huo and Szekely (2016). The algorithm is faster above a certain sample size n. It does not store the distance matrix so the sample size can be very large.

Value

By default, dcov2d returns the V-statistic $V_n = dCov_n^2(x,y)$, and if type="U", it returns the U-statistic, unbiased for $dCov^2(X,Y)$. The argument all.stats=TRUE is used internally when the function is called from dcor2d.

By default, dcor2d returns $dCor_n^2(x,y)$, and if type="U", it returns a bias-corrected estimator of squared dcor equivalent to bcdcor.

These functions do not store the distance matrices so they are helpful when sample size is large and the data is bivariate.

dcov2d 9

Note

The U-statistic U_n can be negative in the lower tail so the square root of the U-statistic is not applied. Similarly, dcor2d(x,y,"U") is bias-corrected and can be negative in the lower tail, so we do not take the square root. The original definitions of dCov and dCor (SRB2007, SR2009) were based on V-statistics, which are non-negative, and defined using the square root of V-statistics.

It has been suggested that instead of taking the square root of the U-statistic, one could take the root of $|U_n|$ before applying the sign, but that introduces more bias than the original dCor, and should never be used.

10 dcovU_stats

doord	11	~ t	- ~	+ ~
dcov	IJ	ST	:a	T.S

Unbiased distance covariance statistics

Description

This function computes unbiased estimators of squared distance covariance, distance variance, and a bias-corrected estimator of (squared) distance correlation.

Usage

```
dcovU_stats(Dx, Dy)
```

Arguments

Dx distance matrix of first sample

Dy distance matrix of second sample

Details

The unbiased (squared) dcov is inner product definition of dCov, in the Hilbert space of U-centered distance matrices.

The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values. The arguments must be square symmetric matrices.

Value

 $dcovU_stats$ returns a vector of the components of bias-corrected dcor: [dCovU, bcdcor, dVarXU, dVarYU].

Note

Unbiased distance covariance (SR2014) corresponds to the biased (original) $d\text{Cov}^2$. Since dcovU is an unbiased statistic, it is signed and we do not take the square root. For the original distance covariance test of independence (SRB2007, SR2009), the distance covariance test statistic is the V-statistic $n d\text{Cov}^2 = n \mathcal{V}_n^2$ (not dCov). Similarly, bcdcor is bias-corrected, so we do not take the square root as with dCor.

Dx <- as.matrix(dist(x))
Dy <- as.matrix(dist(y))
dcovU_stats(Dx, Dy)</pre>
```

disco

distance components (DISCO)

Description

E-statistics DIStance COmponents and tests, analogous to variance components and anova.

Usage

```
disco(x, factors, distance, index=1.0, R, method=c("disco","discoB","discoF"))
disco.between(x, factors, distance, index=1.0, R)
```

Arguments

x data matrix or distance matrix or dist object

factors matrix of factor labels or integers (not design matrix)

distance logical, TRUE if x is distance matrix index exponent on Euclidean distance in (0,2]

R number of replicates for a permutation test

method test statistic

Details

disco calculates the distance components decomposition of total dispersion and if R > 0 tests for significance using the test statistic disco "F" ratio (default method="disco"), or using the between component statistic (method="discoB"), each implemented by permutation test.

If x is a dist object, argument distance is ignored. If x is a distance matrix, set distance=TRUE. In the current release disco computes the decomposition for one-way models only.

12 disco

Value

When method="discoF", disco returns a list similar to the return value from anova.lm, and the print.disco method is provided to format the output into a similar table. Details:

disco returns a class disco object, which is a list containing

call call method

statistic vector of observed statistics

p.value vector of p-values k number of factors

N number of observations

between between-sample distance components

withins one-way within-sample distance components

within within-sample distance component

total total dispersion

Df.trt degrees of freedom for treatments
Df.e degrees of freedom for error
index index (exponent on distance)

factor.names factor names factor.levels factor levels sample.sizes sample sizes

stats matrix containing decomposition

When method="discoB", disco passes the arguments to disco.between, which returns a class htest object.

disco.between returns a class htest object, where the test statistic is the between-sample statistic (proportional to the numerator of the F ratio of the disco test.

Note

The current version does all calculations via matrix arithmetic and boot function. Support for more general additive models and a formula interface is under development.

disco methods have been added to the cluster distance summary function edist, and energy tests for equality of distribution (see eqdist.etest).

distance correlation Distance Correlation and Covariance Statistics

Description

Computes distance covariance and distance correlation statistics, which are multivariate measures of dependence.

14 distance correlation

Usage

```
dcov(x, y, index = 1.0)
dcor(x, y, index = 1.0)
```

Arguments

x data or distances of first sample
y data or distances of second sample
index exponent on Euclidean distance, in (0,2)

Details

dcov and dcor compute distance covariance and distance correlation statistics.

The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values. Arguments x, y can optionally be dist objects; otherwise these arguments are treated as data.

Distance correlation is a new measure of dependence between random vectors introduced by Szekely, Rizzo, and Bakirov (2007). For all distributions with finite first moments, distance correlation \mathcal{R} generalizes the idea of correlation in two fundamental ways: (1) $\mathcal{R}(X,Y)$ is defined for X and Y in arbitrary dimension. (2) $\mathcal{R}(X,Y) = 0$ characterizes independence of X and Y.

Distance correlation satisfies $0 \le \mathcal{R} \le 1$, and $\mathcal{R} = 0$ only if X and Y are independent. Distance covariance \mathcal{V} provides a new approach to the problem of testing the joint independence of random vectors. The formal definitions of the population coefficients \mathcal{V} and \mathcal{R} are given in (SRB 2007). The definitions of the empirical coefficients are as follows.

The empirical distance covariance $\mathcal{V}_n(\mathbf{X},\mathbf{Y})$ with index 1 is the nonnegative number defined by

$$\mathcal{V}_n^2(\mathbf{X}, \mathbf{Y}) = \frac{1}{n^2} \sum_{k,l=1}^n A_{kl} B_{kl}$$

where A_{kl} and B_{kl} are

$$A_{kl} = a_{kl} - \bar{a}_{k.} - \bar{a}_{.l} + \bar{a}_{..}$$

$$B_{kl} = b_{kl} - \bar{b}_{k.} - \bar{b}_{.l} + \bar{b}_{..}$$

Here

$$a_{kl} = ||X_k - X_l||_p$$
, $b_{kl} = ||Y_k - Y_l||_q$, $k, l = 1, ..., n$,

and the subscript . denotes that the mean is computed for the index that it replaces. Similarly, $\mathcal{V}_n(\mathbf{X})$ is the nonnegative number defined by

$$\mathcal{V}_n^2(\mathbf{X}) = \mathcal{V}_n^2(\mathbf{X}, \mathbf{X}) = \frac{1}{n^2} \sum_{k,l=1}^n A_{kl}^2.$$

The empirical distance correlation $\mathcal{R}_n(\mathbf{X}, \mathbf{Y})$ is the square root of

$$\mathcal{R}_n^2(\mathbf{X},\mathbf{Y}) = \frac{\mathcal{V}_n^2(\mathbf{X},\mathbf{Y})}{\sqrt{\mathcal{V}_n^2(\mathbf{X})\mathcal{V}_n^2(\mathbf{Y})}}.$$

See dcov. test for a test of multivariate independence based on the distance covariance statistic.

distance correlation 15

Value

dcov returns the sample distance covariance and dcor returns the sample distance correlation.

Note

Two methods of computing the statistics are provided. dcov and dcor provide R interfaces to the C implementation, which is usually faster. dcov and dcor call an internal function . dcov.

Note that it is inefficient to compute dCor by:

```
square root of dcov(x,y)/sqrt(dcov(x,x)*dcov(y,y))
```

because the individual calls to dcov involve unnecessary repetition of calculations.

Description

Returns the E-distances (energy statistics) between clusters.

Usage

```
edist(x, sizes, distance = FALSE, ix = 1:sum(sizes), alpha = 1,
    method = c("cluster", "discoB"))
```

Arguments

x data matrix of pooled sample or Euclidean distances

sizes vector of sample sizes

distance logical: if TRUE, x is a distance matrix ix a permutation of the row indices of x

alpha distance exponent in (0,2] method how to weight the statistics

Details

A vector containing the pairwise two-sample multivariate \mathcal{E} -statistics for comparing clusters or samples is returned. The e-distance between clusters is computed from the original pooled data, stacked in matrix x where each row is a multivariate observation, or from the distance matrix x of the original data, or distance object returned by dist. The first sizes[1] rows of the original data matrix are the first sample, the next sizes[2] rows are the second sample, etc. The permutation vector ix may be used to obtain e-distances corresponding to a clustering solution at a given level in the hierarchy.

The default method cluster summarizes the e-distances between clusters in a table. The e-distance between two clusters C_i , C_j of size n_i , n_j proposed by Szekely and Rizzo (2005) is the e-distance $e(C_i, C_j)$, defined by

$$e(C_i, C_j) = \frac{n_i n_j}{n_i + n_j} [2M_{ij} - M_{ii} - M_{jj}],$$

where

$$M_{ij} = \frac{1}{n_i n_j} \sum_{p=1}^{n_i} \sum_{q=1}^{n_j} ||X_{ip} - X_{jq}||^{\alpha},$$

 $\|\cdot\|$ denotes Euclidean norm, $\alpha = \text{alpha}$, and X_{ip} denotes the p-th observation in the i-th cluster. The exponent alpha should be in the interval (0,2].

The coefficient $\frac{n_i n_j}{n_i + n_j}$ is one-half of the harmonic mean of the sample sizes. The discoB method is related but with different ways of summarizing the pairwise differences between samples. The disco methods apply the coefficient $\frac{n_i n_j}{2N}$ where N is the total number of observations. This weights each (i,j) statistic by sample size relative to N. See the disco topic for more details.

edist 17

Value

A object of class dist containing the lower triangle of the e-distance matrix of cluster distances corresponding to the permutation of indices ix is returned. The method attribute of the distance object is assigned a value of type, index.

energy-deprecated

Deprecated Functions

Description

These deprecated functions have been replaced by revised functions and will be removed in future releases of the energy package.

Usage

```
dcor.ttest(x, y, distance=FALSE)
dcor.t(x, y, distance=FALSE)
DCOR(x, y, index=1.0)
```

Arguments

x data or distances of first sample
y data or distances of second sample
distance logical: TRUE if x and y are distances
index exponent on Euclidean distance in (0, 2)

Details

* dcor.t has been replaced by dcorT. See dcorT for details. * dcor.ttest has been replaced by dcorT.test. See dcorT.test for details. * DCOR is an R version replaced by faster compiled code.

energy.hclust

Hierarchical Clustering by Minimum (Energy) E-distance

Description

Performs hierarchical clustering by minimum (energy) E-distance method.

Usage

```
energy.hclust(dst, alpha = 1)
```

Arguments

dst dist object alpha distance exponent

energy.hclust 19

Details

Dissimilarities are $d(x,y) = ||x-y||^{\alpha}$, where the exponent α is in the interval (0,2]. This function performs agglomerative hierarchical clustering. Initially, each of the n singletons is a cluster. At each of n-1 steps, the procedure merges the pair of clusters with minimum e-distance. The e-distance between two clusters C_i , C_j of sizes n_i , n_j is given by

$$e(C_i, C_j) = \frac{n_i n_j}{n_i + n_j} [2M_{ij} - M_{ii} - M_{jj}],$$

where

$$M_{ij} = \frac{1}{n_i n_j} \sum_{p=1}^{n_i} \sum_{q=1}^{n_j} ||X_{ip} - X_{jq}||^{\alpha},$$

 $\|\cdot\|$ denotes Euclidean norm, and X_{ip} denotes the p-th observation in the i-th cluster.

The return value is an object of class helust, so helust methods such as print or plot methods, plelust, and cutree are available. See the documentation for helust.

The e-distance measures both the heterogeneity between clusters and the homogeneity within clusters. \mathcal{E} -clustering ($\alpha=1$) is particularly effective in high dimension, and is more effective than some standard hierarchical methods when clusters have equal means (see example below). For other advantages see the references.

edist computes the energy distances for the result (or any partition) and returns the cluster distances in a dist object. See the edist examples.

Value

An object of class hclust which describes the tree produced by the clustering process. The object is a list with components:

merge: an n-1 by 2 matrix, where row i of merge describes the merging of clusters at

step i of the clustering. If an element j in the row is negative, then observation -j was merged at this stage. If j is positive then the merge was with the cluster

formed at the (earlier) stage j of the algorithm.

height: the clustering height: a vector of n-1 non-decreasing real numbers (the e-distance

between merging clusters)

order: a vector giving a permutation of the indices of original observations suitable for

plotting, in the sense that a cluster plot using this ordering and matrix merge will

not have crossings of the branches.

labels: labels for each of the objects being clustered.

call: the call which produced the result.

method: the cluster method that has been used (e-distance).

dist.method: the distance that has been used to create dst.

Note

Currently stats::hclust implements Ward's method by method="ward.D2", which applies the squared distances. That method was previously "ward". Because both hclust and energy use the same type of Lance-Williams recursive formula to update cluster distances, now with the additional

20 energy.hclust

option method="ward.D" in hclust, the energy distance method is easily implemented by hclust. (Some "Ward" algorithms do not use Lance-Williams, however). Energy clustering (with alpha=1) and "ward.D" now return the same result, except that the cluster heights of energy hierarchical clustering with alpha=1 are two times the heights from hclust. In order to ensure compatibility with hclust methods, energy.hclust now passes arguments through to hclust after possibly applying the optional exponent to distance.

eqdist.etest 21

egdist.etest

Multisample E-statistic (Energy) Test of Equal Distributions

Description

Performs the nonparametric multisample E-statistic (energy) test for equality of multivariate distributions.

Usage

```
eqdist.etest(x, sizes, distance = FALSE,
    method=c("original","discoB","discoF"), R)
eqdist.e(x, sizes, distance = FALSE,
    method=c("original","discoB","discoF"))
ksample.e(x, sizes, distance = FALSE,
    method=c("original","discoB","discoF"), ix = 1:sum(sizes))
```

Arguments

x data matrix of pooled sample

sizes vector of sample sizes

distance logical: if TRUE, first argument is a distance matrix

method use original (default) or distance components (discoB, discoF)

R number of bootstrap replicates

ix a permutation of the row indices of x

Details

The k-sample multivariate \mathcal{E} -test of equal distributions is performed. The statistic is computed from the original pooled samples, stacked in matrix x where each row is a multivariate observation, or the corresponding distance matrix. The first sizes[1] rows of x are the first sample, the next sizes[2] rows of x are the second sample, etc.

The test is implemented by nonparametric bootstrap, an approximate permutation test with R replicates.

The function eqdist.e returns the test statistic only; it simply passes the arguments through to eqdist.etest with R = 0.

The k-sample multivariate \mathcal{E} -statistic for testing equal distributions is returned. The statistic is computed from the original pooled samples, stacked in matrix x where each row is a multivariate observation, or from the distance matrix x of the original data. The first sizes[1] rows of x are the first sample, the next sizes[2] rows of x are the second sample, etc.

22 eqdist.etest

The two-sample \mathcal{E} -statistic proposed by Szekely and Rizzo (2004) is the e-distance $e(S_i, S_j)$, defined for two samples S_i, S_j of size n_i, n_j by

$$e(S_i, S_j) = \frac{n_i n_j}{n_i + n_j} [2M_{ij} - M_{ii} - M_{jj}],$$

where

$$M_{ij} = \frac{1}{n_i n_j} \sum_{p=1}^{n_i} \sum_{q=1}^{n_j} ||X_{ip} - X_{jq}||,$$

 $\|\cdot\|$ denotes Euclidean norm, and X_{ip} denotes the p-th observation in the i-th sample.

The original (default method) k-sample \mathcal{E} -statistic is defined by summing the pairwise e-distances over all k(k-1)/2 pairs of samples:

$$\mathcal{E} = \sum_{1 \le i < j \le k} e(S_i, S_j).$$

Large values of \mathcal{E} are significant.

The discoB method computes the between-sample disco statistic. For a one-way analysis, it is related to the original statistic as follows. In the above equation, the weights $\frac{n_i n_j}{n_i + n_j}$ are replaced with

$$\frac{n_i + n_j}{2N} \frac{n_i n_j}{n_i + n_j} = \frac{n_i n_j}{2N}$$

where N is the total number of observations: $N = n_1 + ... + n_k$.

The discoF method is based on the discoF ratio, while the discoB method is based on the between sample component.

Also see disco and disco between functions.

Value

A list with class htest containing

method description of test

statistic observed value of the test statistic
p.value approximate p-value of the test

p. value approximate p-value of the te

data.name description of data

eqdist.e returns test statistic only.

Note

The pairwise e-distances between samples can be conveniently computed by the edist function, which returns a dist object.

24 indep.etest

Description

Pre-computed eigenvalues corresponding to the asymptotic sampling distribution of the energy test statistic for univariate normality, under the null hypothesis. Four Cases are computed:

- 1. Simple hypothesis, known parameters.
- 2. Estimated mean, known variance.
- 3. Known mean, estimated variance.
- 4. Composite hypothesis, estimated parameters.

Case 4 eigenvalues are used in the test function normal.test when method=="limit".

Usage

```
data(EVnormal)
```

Format

Numeric matrix with 125 rows and 5 columns; column 1 is the index, and columns 2-5 are the eigenvalues of Cases 1-4.

Source

Computed

indep.etest

Energy Statistic Test of Independence

Description

Defunct: use indep.test with method = mvI. Computes a multivariate nonparametric E-statistic and test of independence.

Usage

```
indep.e(x, y)
indep.etest(x, y, R)
```

Arguments

x matrix: first sample, observations in rowsy matrix: second sample, observations in rows

R number of replicates

indep.test 25

Details

Computes the coefficient \mathcal{I} and performs a nonparametric \mathcal{E} -test of independence. The test decision is obtained via bootstrap, with R replicates. The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values. The statistic $\mathcal{E} = n\mathcal{I}^2$ is a ratio of V-statistics based on interpoint distances $||x_i - y_j||$. See the reference below for details.

Value

The sample coefficient \mathcal{I} is returned by indep.e. The function indep.etest returns a list with class htest containing

method description of test

 $\begin{array}{ll} \text{statistic} & \text{observed value of the coefficient } \mathcal{I} \\ \text{p.value} & \text{approximate p-value of the test} \end{array}$

data.name description of data

Author(s)

Maria L. Rizzo <mrizzo@bgsu.edu> and Gabor J. Szekely

indep.test Energy-tests of Independence

Description

Computes a multivariate nonparametric test of independence. The default method implements the distance covariance test dcov.test.

Usage

```
indep.test(x, y, method = c("dcov", "mvI"), index = 1, R)
```

Arguments

x matrix: first sample, observations in rows
y matrix: second sample, observations in rows
method a character string giving the name of the test

index exponent on Euclidean distances

R number of replicates

26 indep.test

Details

indep.test with the default method = "dcov" computes the distance covariance test of independence. index is an exponent on the Euclidean distances. Valid choices for index are in (0,2], with default value 1 (Euclidean distance). The arguments are passed to the dcov.test function. See the help topic dcov.test for the description and documentation and also see the references below.

indep.test with method = "mvI" computes the coefficient \mathcal{I}_n and performs a nonparametric \mathcal{E} -test of independence. The arguments are passed to mvI.test. The index argument is ignored (index = 1 is applied). See the help topic mvI.test and also see the reference (2006) below for details.

The test decision is obtained via bootstrap, with R replicates. The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values.

These energy tests of independence are based on related theoretical results, but different test statistics. The dcov method is faster than mvI method by approximately a factor of O(n).

Value

indep. test returns a list with class htest containing

method description of test

statistic observed value of the test statistic nV_n^2 or $n\mathcal{I}_n^2$

estimate $V_n \text{ or } \mathcal{I}_n$

estimates a vector [dCov(x,y), dCor(x,y), dVar(x), dVar(y)] (method dcov)

replicates replicates of the test statistic
p.value approximate p-value of the test

data.name description of data

Note

As of energy-1.1-0, indep.etest is deprecated and replaced by indep.test, which has methods for two different energy tests of independence. indep.test applies the distance covariance test (see dcov.test) by default (method = "dcov"). The original indep.etest applied the independence coefficient \mathcal{I}_n , which is now obtained by method = "mvI".

```

kgroups

K-Groups Clustering

Description

Perform k-groups clustering by energy distance.

Usage

```
kgroups(x, k, iter.max = 10, nstart = 1, cluster = NULL)
```

Arguments

x	Data frame or data matrix or distance object
k	number of clusters
iter.max	maximum number of iterations
nstart	number of restarts
cluster	initial clustering vector

28 kgroups

Details

K-groups is based on the multisample energy distance for comparing distributions. Based on the disco decomposition of total dispersion (a Gini type mean distance) the objective function should either maximize the total between cluster energy distance, or equivalently, minimize the total within cluster energy distance. It is more computationally efficient to minimize within distances, and that makes it possible to use a modified version of the Hartigan-Wong algorithm (1979) to implement K-groups clustering.

The within cluster Gini mean distance is

$$G(C_j) = \frac{1}{n_j^2} \sum_{i,m=1}^{n_j} |x_{i,j} - x_{m,j}|$$

and the K-groups within cluster distance is

$$W_j = \frac{n_j}{2}G(C_j) = \frac{1}{2n_j} \sum_{i,m=1}^{n_j} |x_{i,j} - x_{m,j}|.$$

If z is the data matrix for cluster C_j , then W_j could be computed as sum(dist(z)) / nrow(z).

If cluster is not NULL, the clusters are initialized by this vector (can be a factor or integer vector). Otherwise clusters are initialized with random labels in k approximately equal size clusters.

If x is not a distance object (class(x) == "dist") then x is converted to a data matrix for analysis.

Run up to iter.max complete passes through the data set until a local min is reached. If nstart > 1, on second and later starts, clusters are initialized at random, and the best result is returned.

Value

An object of class kgroups containing the components

call the function call

cluster vector of cluster indices

sizes cluster sizes

within vector of Gini within cluster distances

W sum of within cluster distances

count number of moves
iterations number of iterations
k number of clusters

cluster is a vector containing the group labels, 1 to k. print.kgroups prints some of the components of the kgroups object.

Expect that count is 0 if the algorithm converged to a local min (that is, 0 moves happened on the last iteration). If iterations equals iter.max and count is positive, then the algorithm did not converge to a local min.

mvI.test

Energy Statistic Test of Independence

Description

Computes the multivariate nonparametric E-statistic and test of independence based on independence coefficient \mathcal{I}_n .

Usage

```
mvI.test(x, y, R)
mvI(x, y)
```

30 mvI.test

Arguments

X	matrix: first sample, observations in rows
у	matrix: second sample, observations in rows
R	number of replicates

Details

Computes the coefficient \mathcal{I} and performs a nonparametric \mathcal{E} -test of independence. The test decision is obtained via bootstrap, with R replicates. The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values. The statistic $\mathcal{E}=n\mathcal{I}^2$ is a ratio of V-statistics based on interpoint distances $\|x_i-y_j\|$. See the reference below for details.

Value

mvI returns the statistic. mvI. test returns a list with class htest containing

method description of test statistic observed value of the test statistic $n\mathcal{I}_n^2$ estimate \mathcal{I}_n replicates replicates of the test statistic p.value approximate p-value of the test data.name description of data

Note

Historically this is the first energy test of independence. The distance covariance test dcov.test, distance correlation dcor, and related methods are more recent (2007,2009). The distance covariance test is faster and has different properties than mvI.test. Both methods are based on a population independence coefficient that characterizes independence and both tests are statistically consistent.

mvnorm.test 31

mvnorm.test

E-statistic (Energy) Test of Multivariate Normality

Description

Performs the E-statistic (energy) test of multivariate or univariate normality.

Usage

```
mvnorm.test(x, R)
mvnorm.etest(x, R)
mvnorm.e(x)
```

Arguments

x data matrix of multivariate sample, or univariate data vector

R number of bootstrap replicates

Details

If x is a matrix, each row is a multivariate observation. The data will be standardized to zero mean and identity covariance matrix using the sample mean vector and sample covariance matrix. If x is a vector, mvnorm.e returns the univariate statistic normal.e(x). If the data contains missing values or the sample covariance matrix is singular, mvnorm.e returns NA.

The \mathcal{E} -test of multivariate normality was proposed and implemented by Szekely and Rizzo (2005). The test statistic for d-variate normality is given by

$$\mathcal{E} = n\left(\frac{2}{n}\sum_{i=1}^{n} E||y_i - Z|| - E||Z - Z'|| - \frac{1}{n^2}\sum_{i=1}^{n}\sum_{j=1}^{n}||y_i - y_j||\right),$$

where y_1, \ldots, y_n is the standardized sample, Z, Z' are iid standard d-variate normal, and $\|\cdot\|$ denotes Euclidean norm.

The \mathcal{E} -test of multivariate (univariate) normality is implemented by parametric bootstrap with R replicates.

Value

The value of the \mathcal{E} -statistic for multivariate normality is returned by mvnorm.e.

mvnorm. test returns a list with class htest containing

method description of test

statistic observed value of the test statistic p.value approximate p-value of the test

data.name description of data

mvnorm.etest is replaced by mvnorm.test.

32 normal.test

Note

If the data is univariate, the test statistic is formally the same as the multivariate case, but a more efficient computational formula is applied in normal.e.

normal.test also provides an optional method for the test based on the asymptotic sampling distribution of the test statistic.

## test if the iris Setosa data has multivariate normal distribution
mvnorm.test(iris[1:50,1:4], R = 199)
```

normal.test

Energy Test of Univariate Normality

Description

Performs the energy test of univariate normality for the composite hypothesis Case 4, estimated parameters.

Usage

```
normal.test(x, method=c("mc","limit"), R)
normal.e(x)
```

normal.test 33

Arguments

x univariate data vector method method for p-value

R number of replications if Monte Carlo method

Details

If method="mc" this test function applies the parametric bootstrap method implemented in mynorm. test.

If method="limit", the p-value of the test is computed from the asymptotic distribution of the test statistic under the null hypothesis. The asymptotic distribution is a quadratic form of centered Gaussian random variables, which has the form

$$\sum_{k=1}^{\infty} \lambda_k Z_k^2,$$

where λ_k are positive constants (eigenvalues) and Z_k are iid standard normal variables. Eigenvalues are pre-computed and stored internally. A p-value is computed using Imhof's method as implemented in the **CompQuadForm** package.

Note that the "limit" method is intended for moderately large samples because it applies the asymptotic distribution.

The energy test of normality was proposed and implemented by Szekely and Rizzo (2005). See mynorm, test for more details.

Value

normal.e returns the energy goodness-of-fit statistic for a univariate sample.

normal.test returns a list with class htest containing

statistic observed value of the test statistic

p.value p-value of the test

estimate sample estimates: mean, sd

data.name description of data

34 pdcor

See Also

mvnorm. test and mvnorm. e for the energy test of multivariate normality and the test statistic for multivariate samples.

Examples

```
x <- iris[1:50, 1]
normal.e(x)
normal.test(x, R=199)
normal.test(x, method="limit")</pre>
```

pdcor

Partial distance correlation and covariance

Description

Partial distance correlation pdcor, pdcov, and tests.

Usage

```
pdcov.test(x, y, z, R)
pdcor.test(x, y, z, R)
pdcor(x, y, z)
pdcov(x, y, z)
```

Arguments

X	data matrix or dist object of first sample
у	data matrix or dist object of second sample
Z	data matrix or dist object of third sample
R	replicates for permutation test

Details

pdcor(x,y,z) and pdcov(x,y,z) compute the partial distance correlation and partial distance covariance, respectively, of x and y removing z.

A test for zero partial distance correlation (or zero partial distance covariance) is implemented in pdcor.test, and pdcov.test.

If the argument is a matrix, it is treated as a data matrix and distances are computed (observations in rows). If the arguments are distances or dissimilarities, they must be distance (dist) objects. For symmetric, zero-diagonal dissimilarity matrices, use as .dist to convert to a dist object.

Value

Each test returns an object of class htest.

Examples

```
n = 30
R <- 199
## mutually independent standard normal vectors
x <- rnorm(n)</pre>
y <- rnorm(n)
z <- rnorm(n)</pre>
pdcor(x, y, z)
pdcov(x, y, z)
set.seed(1)
pdcov.test(x, y, z, R=R)
set.seed(1)
pdcor.test(x, y, z, R=R)
if (require(MASS)) {
  p = 4
 mu <- rep(0, p)
 Sigma <- diag(p)
  ## linear dependence
 y <- mvrnorm(n, mu, Sigma) + x
 print(pdcov.test(x, y, z, R=R))
  ## non-linear dependence
 y <- mvrnorm(n, mu, Sigma) * x
 print(pdcov.test(x, y, z, R=R))
```

Poisson Tests

Goodness-of-Fit Tests for Poisson Distribution

Description

Performs the mean distance goodness-of-fit test and the energy goodness-of-fit test of Poisson distribution with unknown parameter.

Usage

```
poisson.e(x)
poisson.m(x)
poisson.etest(x, R)
poisson.mtest(x, R)
poisson.tests(x, R, test="all")
```

Arguments

x vector of nonnegative integers, the sample data

R number of bootstrap replicates

test name of test(s)

Details

Two distance-based tests of Poissonity are applied in poisson.tests, "M" and "E". The default is to do all tests and return results in a data frame. Valid choices for test are "M", "E", or "all" with default "all".

If "all" tests, all tests are performed by a single parametric bootstrap computing all test statistics on each sample.

The "M" choice is two tests, one based on a Cramer-von Mises distance and the other an Anderson-Darling distance. The "E" choice is the energy goodness-of-fit test.

R must be a positive integer for a test. If R is missing or 0, a warning is printed but test statistics are computed (without testing).

The mean distance test of Poissonity (M-test) is based on the result that the sequence of expected values EIX-jI, j=0,1,2,... characterizes the distribution of the random variable X. As an application of this characterization one can get an estimator $\hat{F}(j)$ of the CDF. The test statistic (see poisson.m) is a Cramer-von Mises type of distance, with M-estimates replacing the usual EDF estimates of the CDF:

$$M_n = n \sum_{j=0}^{\infty} (\hat{F}(j) - F(j; \hat{\lambda}))^2 f(j; \hat{\lambda}).$$

In poisson. tests, an Anderson-Darling type of weight is also applied when test="M" or test="all".

The tests are implemented by parametric bootstrap with R replicates.

An energy goodness-of-fit test (E) is based on the test statistic

$$Q_n = n\left(\frac{2}{n}\sum_{i=1}^n E|x_i - X| - E|X - X'| - \frac{1}{n^2}\sum_{i,j=1}^n |x_i - x_j|,\right)$$

where X and X' are iid with the hypothesized null distribution. For a test of H: $X \sim Poisson(\lambda)$, we can express E[X-X'] in terms of Bessel functions, and $E[x_i - X]$ in terms of the CDF of $Poisson(\lambda)$.

If test=="all" or not specified, all tests are run with a single parametric bootstrap. poisson.mtest implements only the Poisson M-test with Cramer-von Mises type distance. poisson.etest implements only the Poisson energy test.

Poisson Tests 37

Value

The functions poisson.m and poisson.e return the test statistics. The function poisson.mtest or poisson.etest return an htest object containing

method Description of test

statistic observed value of the test statistic p.value approximate p-value of the test

 $\begin{array}{ll} \mbox{data.name} & \mbox{replicates} \ R \\ \mbox{estimate} & \mbox{sample} \ \mbox{mean} \end{array}$

poisson.tests returns "M-CvM test", "M-AD test" and "Energy test" results in a data frame with columns

estimate sample mean

statistic observed value of the test statistic p.value approximate p-value of the test

method Description of test

which can be coerced to a tibble.

Note

The running time of the M test is much faster than the E-test.

```

38 sortrank

sortrank

Sort, order and rank a vector

Description

A utility that returns a list with the components equivalent to sort(x), order(x), rank(x), ties.method = "first").

Usage

```
sortrank(x)
```

Arguments

Χ

vector compatible with sort(x)

Details

This utility exists to save a little time on large vectors when two or all three of the sort(), order(), rank() results are required. In case of ties, the ranks component matches rank(x, ties.method = "first").

Value

A list with components

x the sorted input vector x

ix the permutation = order(x) which rearranges x into ascending order

r the ranks of x

Note

This function was benchmarked faster than the combined calls to sort and rank.

Author(s)

```
Maria L. Rizzo <mrizzo@bgsu.edu>
```

References

```
See sort.
```

```
sortrank(rnorm(5))
```

Unbiased distance covariance

Unbiased dcov and bias-corrected dcor statistics

Description

These functions compute unbiased estimators of squared distance covariance and a bias-corrected estimator of (squared) distance correlation.

Usage

```
bcdcor(x, y)
dcovU(x, y)
```

Arguments

x data or dist object of first sample

y data or dist object of second sample

Details

The unbiased (squared) dcov is inner product definition of dCov, in the Hilbert space of U-centered distance matrices.

The sample sizes (number of rows) of the two samples must agree, and samples must not contain missing values. Arguments x, y can optionally be dist objects; otherwise these arguments are treated as data.

Value

dcovU returns the unbiased estimator of squared dcov. bcdcor returns a bias-corrected estimator of squared dcor.

Note

Unbiased distance covariance (SR2014) corresponds to the biased (original) $d\text{Cov}^2$. Since dcovU is an unbiased statistic, it is signed and we do not take the square root. For the original distance covariance test of independence (SRB2007, SR2009), the distance covariance test statistic is the V-statistic $n d\text{Cov}^2 = n \mathcal{V}_n^2$ (not dCov). Similarly, bcdcor is bias-corrected, so we do not take the square root as with dCor.

bcdcor(x, y)</pre>
```

U_product

Inner product in the Hilbert space of U-centered distance matrices

Description

Stand-alone function to compute the inner product in the Hilbert space of U-centered distance matrices, as in the definition of partial distance covariance.

Usage

```
U_product(U, V)
```

Arguments

U U-centered distance matrix
V U-centered distance matrix

Details

Note that pdcor, etc. functions include the centering and projection operations, so that these stand alone versions are not needed except in case one wants to check the internal computations.

Exported from U_product.cpp.

Value

U_product returns the inner product, a scalar.
